## **Safety Multiclass Incremental Transfer Learning**

#### **Abstract**

It is always challenging for a model to adapt new categories. Transfer learning suggests that leveraging the knowledge from existing models and data can help the model to learn new categories. However, in some cases, we are not able to access the source data. To leverage the knowledge from the source models (called hypotheses), Hypothesis Transfer Learning (HTL) is proposed to learn the new category in this scenario where we can only access the models. In practical HTL, without accessing the source data, we have to evaluate the source hypotheses in the target task, for each category, to avoid degraded performance (negative transfer). In this paper, we propose our method, called Safety Multiclass Incremental Transfer Learning (SMI-TLe). SMITLe can safely utilize each source hypothesis effectively. We show that the transfer parameters learned from SMITLe can avoid negative transfer and our algorithm converges at the rate of  $O(\frac{\log(t)}{t})$ . We design 3 sets of experiment that would happen in real learning scenario. Experimental results show that SMITLe can consistently achieve higher accuracy compared to previous methods.

#### 1 Introduction

The success of transfer learning suggests that exploiting the knowledge of the existing models properly can greatly help us to learn new categories. Transfer learning on image recognition is a very popular topic in recent years. It is important for a classifier to learn the new categories continuously. To adapt multiple categories, the classifier can adapt one category each time iteratively, i.e. extending the source N-category classifier to a target N+1 one. Previous approaches show that, to add the new category to the existing classifier, leveraging the knowledge from source data and models can help this learning procedure effectively [Tommasi  $et\ al.$ , 2014] [Kuzborskij  $et\ al.$ , 2013]. However, in some cases, we can only obtain the source models and it is difficult to access their training data. For instance, it becomes a common practice to reuse a trained object recognition model on new tasks without accessing the

large-scale source image dataset. Recently, some works have been proposed within a framework called Hypothesis Transfer Learning (HTL) to handle this situation [Kuzborskij and Orabona, 2013]. HTL assumes only source models (called hypothesis) trained on source task can be utilized and there is no access to source data, nor any knowledge about the relatedness of the source and target distributions.

In HTL, a number of works have been attempted with Least Square Support Vector Machine (LS-SVM) [Kuzborskij and Orabona, 2013]. Previous approaches show that the hypotheses can be evaluated effectively with LS-SVM via Leave-One-Out cross-validation [Tommasi et al., 2014]. The framework of HTL with LS-SVM has two major phrases: (I) Building binary One-Versus-All SVMs with transfer parameters. (II) Estimating the transfer parameters. Previous methods of HTL assume that the hypotheses of the N categories are correct for the corresponding categories in the target task, e.g. the source hypothesis to distinguish the orange and apple also works for the orange and apple in target task[Kuzborskij et al., 2013]. However, the source hypothesis may fail in target task. For example, a source hypothesis is trained from to distinguish apple and orange using the images that are bright and have high contrast level, but the images of orange and apple collected by us could be low contrast and taken in a dark environment. Therefore, it is trivial to assume that the prior hypotheses are also correct for the data in the target task.

In this paper, we extend previous methods by relaxing the assumption that the hypotheses from source task are correct the same category. When the source hypotheses fail, transferring from them could lead to negative transfer. In transfer learning, when the data distribution of the source and target task are similar, transferring the knowledge between them can improve the performance of the classifier for the target one, which is called positive transfer. On the other hand, when the data distribution is different, leveraging the knowledge could even degrade the performance of the classifier on target task, which is referred to as negative transfer [Pan and Yang, 2010]. In the worst case of HTL, where all hypotheses fail, transfer learning algorithms may suffer from negative transfer due to the mismatched data distribution. In our case, this mismatched distribution can result from both the N original categories and the new added category (see Figure 1).

Previous methods of HTL focus on how to leverage the knowledge for the new category and are not able to avoid neg-

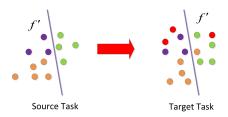

Figure 1: Negative transfer happens when we transfer prior hypothesis f' to target one. Points with different color represent different categories. The data distribution would change even for identical categories in different task. The new added category (red points) can also greatly affect the data distribution in target task.

ative transfer, especially when all the hypotheses fails (see experiments in Section 4). In this paper, we propose our method, called Safety Multiclass Incremental Transfer Learning (SMITLe), that can both avoid negative transfer and leverage correct hypotheses. The main contributions of this paper include: (1) We propose a novel algorithm SMITLe within the HTL framework that can safely utilize the prior hypotheses to prevent negative transfer. (2) We also show that SMI-TLe can obtain the optimal solution at the rate of  $O(\frac{\log(t)}{t})$ where t is training iteration. Following the two phrases of HTL, in Phrase I, to train the binary models for the target task, we propose an objective function with transfer parameters that can control the amount of knowledge from the hypotheses. In Phrase II, to measure the transferability of each prior hypothesis, we estimate our transfer parameters using multi-class prediction error based on closed-form leave-oneout (LOO) error for model evaluation. Moreover, we propose our novel objective function that can balance the weight between the prior hypotheses and empirical knowledge from target task. We prove that, transfer parameters learned from our novel objection function can avoid negative transfer. Experimental results show that SMITLe can achieve better accuracy than other existing baselines.

The rest of this paper is organized as follow. In Section 2, we introduce the biased regularization terms of our problem for phrase 1 of HTL. Then, we propose a novel objective function for transfer parameter estimation, called SMITLe in Section 3. We show that the estimated transfer parameter can distinguish the utility of the prior hypothesis and avoid negative transfer autonomously. In Section 4, we show the performance comparison between SMITLe and other baselines on a variety of experiments on AwA and Caltech datasets in three different scenarios.

#### 2 Biased Regularization

In this section, we focus on the Phrase I of HTL and introduce our biased regularization for binary LS-SVM for our problem. We use multi-source transfer strategy to generate our biased regularization. As a result, the decision of each binary LS-SVM is the linear combination of the knowledge from both target task and source hypotheses controlled by certain transfer parameters.

We define our task in the following way: assume that, for

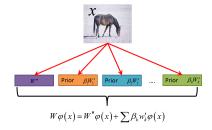

Figure 2: The final decision function value of a binary SVM can be get by combining the prior and empirical knowledge.

our (N+1)-category target task,  $x \in \mathcal{X}$  and  $y \in Y = \{1,2,...,N+1\}$  are the input vector and output for the learning task respectively. Meanwhile, we have a set of binary linear classifiers (hypotheses)  $f_n'(x) = \phi(x)w_n' + b_n'$ , for n=1,...,N trained from an unknown distribution with One-Versus-All (OVA) strategy. Now we want to learn a set of classifiers  $f_n(x) = \phi(x)w_n + b_n, n = 1,...,N+1$  for our new task. The example x is assigned to the category y if  $y \equiv \arg\max_{n=1,...,N+1} \{f_n(x)\}$ . From previous works of HTL, the solution of the parameters y in y is a solution of the parameters y in y i

min 
$$R(w_n, W') + \frac{C}{2} \sum_{i}^{l} (Y_{i,n} - \phi(x_i)w_n - b_n)^2$$

Here,  $W' = \{w'_1, w'_2, ..., w'_n\}$ .  $R(w_n, W')$  is the regularization term to guarantee good transfer performance and avoid overfitting. Y is a encoded label matrix so that  $Y_{in} = 1$  if  $y_i = n$  and -1 otherwise.

Now our task can be divided into two separate part: learning the the  $(N+1)_{th}$  new category and N overlapped categories.

For the new added category, it is very difficult to identify the utility of the hypothesis of a single category in source task, therefore, we use multi-source transfer strategy, adopted from Multi-KT [Tommasi *et al.*, 2014], to leverage hypotheses from multiple sources. As a result, regularization term  $R(w_{N+1}, W')$  can be written as:

$$R(w_{N+1}, W') = \frac{1}{2} \left\| w_{N+1} - \sum_{k=1}^{N} w'_k \beta_k \right\|^2 \tag{1}$$

We can interpret the biased regularization in the following way. Let  $w_{N+1}=w_{N+1}''+\sum \beta_k w_k'$  (See Figure 2). Therefore, we have:

$$w_{N+1}\phi(x) = w_{N+1}''\phi(x) + \sum \beta_k w_k'\phi(x)$$

Here, we call  $\beta$  the transfer parameter. For any fixed value of  $\beta$ , regularizing  $w_n$  is equivalent to regularize  $w_{N+1}''$ , i.e.  $(w_{N+1} - \sum \beta_k w_k')$ . The decision of each binary SVM model is made by combining the decision from target task  $w_{N+1}''\phi(x)$  and source hypotheses  $w_k'\phi(x)$  controlled by the transfer parameter. The amount of transfered knowledge has a positive correlation to the value of  $\beta$ .

However, for the original N categories, we already have their corresponding source category hypotheses and thus, their regularization term can be written as:

$$R(w_n, w'_n) = \frac{1}{2} \|w_n - \gamma_n w'_n\|^2$$
 (2)

As we can see that the regularization term (2) is a special case of (1) where only one  $\beta_k$  is none-zero.

Combining these two together, our multi-class incremental transfer problem can be solved by optimizing the following objective function:

$$\min \frac{1}{2} \sum_{n=1}^{N} \|w_n - \gamma_n w'_n\|^2 + \frac{1}{2} \|w_{N+1} - \sum_{k=1}^{N} w'_k \beta_k\|^2 + \frac{C}{2} \sum_{n=1}^{N+1} \sum_{i=1}^{l} e_{i,n}^2$$

**s.t.** 
$$e_{i,n} = Y_{in} - \phi(x_i)w_n - b_n, \quad n \in \{1, ..., N+1\}$$

The optimal solution to Eq. (3) is:

$$w_{n} = \gamma_{n} w'_{n} + \sum_{i}^{l} \alpha_{in} \phi(x_{i}), n = 1, ..., N$$

$$w_{N+1} = \sum_{k}^{N} \beta_{k} w'_{k} + \sum_{i}^{l} \alpha_{i(N+1)} \phi(x_{i})$$
(4)

Here  $\alpha_{ij}$  is the element (i, j) in  $\alpha$ .

Let K(X, X) be the kernel matrix and

$$\psi = \begin{bmatrix} K(X,X) + \frac{1}{C}I & \mathbf{1} \\ \mathbf{1}^{\mathbf{T}} & 0 \end{bmatrix}$$
 (5)

$$\psi \begin{bmatrix} \boldsymbol{\alpha}' \\ \boldsymbol{b}' \end{bmatrix} = \begin{bmatrix} Y \\ 0 \end{bmatrix}, \quad \psi \begin{bmatrix} \boldsymbol{\alpha}'' \\ \boldsymbol{b}'' \end{bmatrix} = \begin{bmatrix} X(W')^T \\ 0 \end{bmatrix} \quad (6)$$

We have:

$$\alpha = \alpha' - \left[ \begin{array}{cc} \alpha'' d_{\gamma} & \alpha'' \beta^T \end{array} \right] \tag{7}$$

Here  $d_{\gamma}$  is a diagonal matrix with  $\{\gamma_i\}_{i=1,\dots,N}$  in its main diagonal. From Eq. (7) we can see that, the solution of Eq. (3) is completed once  $\gamma$  and  $\beta$  are set.

## 3 SMITLe

In this section, we focus on the Phrase II of HTL, to estimate the transfer parameter in our task. We introduce an algorithm, called SMITLe, that can effectively estimate unbiased transfer parameter from small training set.

## 3.1 Multi-class Prediction Loss with LOO

From Phrase I, we can see that the amount of knowledge transfered is determined by the transfer parameter  $\gamma$  and  $\beta$ . Generally, we would like to reduce the amount of transfer from the prior hypotheses when they are incorrect. Meanwhile, for those correct ones, aggressively increasing the amount of transfer can boost the performance for the target problem. Once we fix the value of  $\gamma$  and  $\beta$ , our task can be directly solved.

To evaluate different settings of  $\gamma$  and  $\beta$ , we have to their cross-validation error iteratively. In this paper, we choose the Leave-One-Out (LOO) cross-validation error as the evaluation criterion. We choose it for the following two reasons: (1) It is proven that LOO error has low bias on small training data regime [Kuzborskij and Orabona, 2013]. (2) Moreover, it is exhausted to really perform cross-validations and compare the results for each setting of  $(\gamma, \beta)$ . An important advantage of choosing LS-SVM over the other model is that we can obtain unbiased LOO error in closed form without real performing it.

The unbiased LOO estimation for sample  $x_i$  can be written as [Cawley, 2006]:

$$\hat{Y}_{i,n} = Y_{i,n} - \frac{\alpha_{in}}{\psi_{ii}^{-1}}$$
 for  $n = 1, ..., N + 1$  (8)

Here  $\psi^{-1}$  is the inverse of matrix  $\psi$  and  $\psi_{ii}^{-1}$  is the ith diagonal element of  $\psi^{-1}$ .

Let us call  $\xi_i$  the multi-class prediction error for example  $x_i$ .  $\xi_i$  can be defined as [Crammer and Singer, 2002]:

$$\xi_{i}(\gamma, \beta) = \max_{n \in \{1, \dots, N+1\}} \left[ 1 - \varepsilon_{ny_{i}} + \hat{Y}_{in}(\gamma, \beta) - \hat{Y}_{iy_{i}}(\gamma, \beta) \right]$$

$$(9)$$

Where  $\varepsilon_{ny_i} = 1$  if  $n = y_i$  and 0 otherwise. The intuition behind this loss function is to enforce the distance between the true class and other classes to be at least 1.

Now, we already have an effective way to measure the performance of different settings of  $\gamma$  and  $\beta$  for our task. In the next part, we introduce how we optimize these parameters.

#### 3.2 Loss Function of SMITLe

In this part, we propose a novel objective function according to our multi-class prediction loss function for transfer parameter estimation. We show that we can effectively obtain the optimal  $\gamma$  and  $\beta$  that is resistant to negative transfer.

From (9) we can see that, different from the binary scenario where 0 is used as the hard threshold to distinguish the two classes, our multi-class loss only depends on the gap between the decision function value of the correct label  $(\hat{Y}_{y_i})$  and the maximum among the decision function value of the other labels  $\hat{Y}_{in}(n \neq y_i)$ . To reduce  $\xi_i$  for a specific example  $x_i$ , we only have to increase the gap between  $\hat{Y}_{in}(n \neq y_i)$  and  $\hat{Y}_{iy_i}$ .

As we mentioned before, the amount of knowledge transfered is positively correlated to the value of transfer parameter. When the prior hypotheses are correct, we have  $w'_{y_i}\phi(x_i)>w'_n\phi(x_i)$ . If  $\xi_i>0$ , increasing the transfer parameters can reduce the gap between  $\hat{Y}_{y_i}$  and  $\hat{Y}_{in}(n\neq y_i)$ , leading to smaller  $\xi_i$ . When the prior hypotheses are incorrect and  $\xi_i>0$ , there exists a  $j(j\neq y_i)$  such that  $w'_{y_i}\phi(x_i)< w'_j\phi(x_i)$ . Thus, reducing the transfer parameter can eventually reduce  $\xi_i$ .

Instead of optimize  $\xi_i$  directly, we add two extra regularization terms for  $\gamma$  and  $\beta$ . Then we define our objective function

Here  $\lambda_1$  and  $\lambda_2$  are two regularization parameters to prevent negative transfer. By adding these two regularization terms, the objective function (10) turns to be strongly convex. Therefore, its strongly convex property guarantees that SMITLe can converge at the rate of  $O(\frac{\log(t)}{t})$  (see proof in Appendix A).

From the objective function above we can see that, for certain  $\lambda_1$  and  $\lambda_2$ , when the prior hypotheses are incorrect and harmful, decreasing  $\gamma$  and  $\beta$  leads to smaller loss from both regularization and multi-class prediction error for target task. Moreover, we also prove that with optimal  $\gamma$  and  $\beta$  from this objective function, SMITLe can actually avoid negative transfer (see Appendix B). On the other hand, if the prior hypotheses are incorrect, even though, increasing  $\gamma$  and  $\beta$  leads to larger regularization loss, it also leads to smaller multi-class prediction error on the target problem. Therefore, the algorithm compromises between them.

## 3.3 Optimizing $\gamma$ and $\beta$

By adding a dual set of variables in objective function (10), one for each constraint in, we get the Lagrangian of the optimization problem:

$$L\left(\gamma, \beta, \xi, \eta\right) = \frac{\lambda_{1}}{2} \sum_{n=1}^{N} \left\|\gamma_{n}\right\|^{2} + \frac{\lambda_{2}}{2} \sum_{n=1}^{N} \left\|\beta_{n}\right\|^{2} + \sum_{i=1}^{l} \xi_{i}$$

$$+ \sum_{i,n} \eta_{i,n} \left[1 - \varepsilon_{ny_{i}} + \hat{Y}_{in}\left(\gamma, \beta\right) - \hat{Y}_{iy_{i}}\left(\gamma, \beta\right) - \xi_{i}\right]$$
**s.t.**  $\forall i, n \quad \eta_{i,n} \geq 0$ 

$$(11)$$

To obtain the optimal values for the problem above, we introduce our method using sub-gradient descent [Boyd and Vandenberghe, 2004] and summarize it in Algorithm. 1.

## 4 Experiment

In this section, we show empirical results of our algorithm on different transferring situations on two datasets: AwA10<sup>1</sup> [Lampert *et al.*, 2009] and Caltech10<sup>2</sup> [Griffin *et al.*, 2007]. In real world applications, there are three situations in HTL. The first two extreme cases are all the hypotheses are correct/incorrect. The third one is the intermediate (mixed) case where only part of the hypotheses are correct. We design three sets of experiment, called positive, negative and mixed transfer experiment respectively, based on these 3 situations, comparing our algorithm with the baselines.

#### Algorithm 1 SMITLe optimization

```
\begin{array}{ll} \textbf{Input:} \;\; \psi,\alpha',\alpha'',T,\psi,\\ \textbf{Output:} \;\; \gamma = \left\{\gamma^1,...,\gamma^n\right\},\beta\\ 1: \;\; \beta^0 \leftarrow 0,\gamma^0 \leftarrow 1 \end{array}
     2: for t = 1 to T do
                       \hat{Y} \leftarrow Y - (\psi \circ I)^{-1} \left( \alpha' - \left[ \alpha'' d_{\gamma} \quad \alpha'' \beta^T \right] \right)
                         \Delta_{\gamma} = 0, \Delta_{\beta} = 0
     4:
                         for i = 1 to l do
     5:
                                 \Delta_{\gamma} \leftarrow \Delta_{\gamma} + \lambda_1 \gamma, \Delta_{\beta} \leftarrow \Delta_{\beta} + \lambda_2 \beta
     6:
     7:

  19:
                        \beta^t \leftarrow \beta^{(t-1)} - \frac{\Delta_{\beta}}{l \times t}, \gamma^t \leftarrow \gamma^{(t-1)} - \frac{\Delta_{\gamma}}{l \times t}
 20:
 21: end for
```

#### 4.1 Dataset

Caltch10 is a subset of Caltech256. We select the following 10 categories: bat, bear, dolphin, giraffe, gorilla, horse, leopard, raccoon, skunk, zebra, containing 1387 images, as our dataset. AwA10 is a sub set of AwA dataset. We choose the identical 10 categories as those in Caltech10 from it, containing 6917 images.

#### 4.2 Baselines and algorithmic setup

We compare our algorithm with two kinds of baselines. The first one is methods without leveraging any prior knowledge (no transfer baselines). The second consists of some methods with transfer techniques.

We select 3 no transfer baselines: **No transfer:** LS-SVM trained only on target data. Any transfer algorithm that performs worse than it suffers from negative transfer. **Batch:** We combined the source and target data, assuming that we have fully access to all data, to train the LS-SVM. The result of this baseline might be considered as the best performance achieved when the hypotheses are correct. We only perform this baseline in positive transfer experiment. **Source+1:** This method only train a new binary LS-SVM for the new category. For the rest of the classes, we use the predictions of the classifiers trained from source data directly. Its performance indicates the correctness of the hypotheses.

We select the 3 HTL methods, MKTL [Jie *et al.*, 2011], MULTI-KT [Tommasi *et al.*, 2014] and MULTIPLE [Kuzborskij *et al.*, 2013], as our transfer baselines.

For all the experiments in this section, we adopt the same strategy as [Kuzborskij et al., 2013] and [Tommasi

<sup>&</sup>lt;sup>1</sup>The features of AwA dataset is available from http://attributes.kyb.tuebingen.mpg.de/

<sup>&</sup>lt;sup>2</sup>Images for Caltech is available from http://www.vision.caltech.edu/Image\_Datasets/Caltech256/

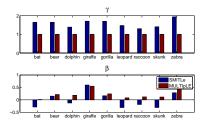

Figure 3: Experiment results for 10 classes, AwA. Horse is used as the new category. We can see that SMITLe tends to more aggressively exploit the related prior knowledge.

et al., 2014], using kernel averaging [Gehler and Nowozin, 2009] to compute the average of RBF kernels over the available features on RBF hyperparameter  $\{2^{-5}, 2^{-4}, ..., 2^8\}$ . The penalty parameter C is tuned via cross-validation on  $\{10^{-5}, 10^{-4}, ..., 10^8\}$  and the optimal value is reused for all the algorithms. Two transfer regularization parameters  $\lambda 1$  and  $\lambda 2$  are also set via cross-validation on  $\{10^{-3}, 10^{-2}, ..., 10\}$  respectively.

# **4.3** Positive transfer: transferring from correct hypotheses

In the extreme case, where the hypotheses are correct, the data of the source and target tasks should be drawn from the same distribution. Thus we perform two experiments under this setting on both AwA and Caltech. For each dataset, we split the data into two sets. One is treated as the source dataset to train the source hypotheses and another is treated as the target dataset for training and testing. We iteratively choose one category as the new category and run the experiment 10 times. Due to space constraint, we only report the average results of the two experiments in Table 1 and Table 2. From the results we can see that, SMITLe can achieve high classification accuracy than other baselines in most of the cases.

To illustrate the detail performance of our algorithm, we select the experiment result on AwA dataset where horse is chosen as the new category for further explanation. In Figure 3 we provide values of  $\gamma$  and  $\beta$  compared with the parameters of the runner-up transfer algorithm MULTIpLE. We can see that for transfer knowledge between identical categories, MULTIPLE fixes the transfer parameter ( $\gamma$ ) to be 1 while our method sets greater weights for related prior knowledge. By exploiting the positive prior knowledge more aggressively, SMITLe is able to leverage the prior knowledge and outperforms other methods. For the transfer parameter  $\beta$  we can see that MULTIpLE tends to keep  $\beta$  greater than 0 and SMI-TLe works more intuitively, setting positive weight for related categories(giraffe, zebra and bear etc.) and small or even negative weight for unrelated categories (bat, dolphin and skunk etc.).

## 4.4 Negative transfer: transferring from incorrect hypotheses

In this section, we show how our method performs in transferring knowledge between two different datasets, from AwA dataset to Caltech dataset. Following the settings in previous

Table 1: Average accuracy in percentage across all categories from Caltech to Caltech with different size of training set in target problem. 30 examples are randomly chosen from each class to train the source classifier and 30 examples from each class are chosen for test.

# per category	5	10	15	20
No transfer	27.33	31.53	35.73	38.47
Source+1	43.33	43.87	44.33	44.57
MKTL	38.89	43.27	45.72	47.44
MULTIKT	37.96	42.89	45.96	47.32
MULTIpLE	42.63	45.63	47.81	48.73
SMITLe	43.53	46.45	48.25	49.15
Batch	43.77	44.73	46.67	48.00

Table 2: Average accuracy in percentage across all categories from AwA to AwA with different size of training set in target problem. 50 examples are randomly chosen from each class to train the source classifier and 200 examples from each class are chosen for test.

# per category	5	10	15	20
No transfer	23.52	26.79	29.60	31.50
Source+1	39.00	39.34	39.62	39.74
MKTL	31.46	34.76	37.41	38.81
MULTIKT	29.86	32.86	35.22	36.33
MULTIpLE	37.80	38.81	39.80	40.47
SMITLe	37.83	39.31	40.37	41.09
Batch	39.62	40.18	40.67	41.44

experiment, the source models are trained from AwA dataset and transfered to Caltech dataset. We show the average performance of each algorithm in Table 3. We can see that negative transfer does happen when transferring the knowledge from AwA to Caltech for all the algorithms except for ours. From the performance of Source+1, we can see that applying the source hypotheses directly leads to poor performance. We can conclude that even though these two datasets share some categories, the data distribution of the feature representation for the same category is not consistent.

Still we take the experiment where horse is considered as the new category to see the detail performance of each algorithm. From here we can see that, not surprisingly, the accuracy of SMITLe shows similar accuracy to the no transfer baseline, while other methods suffer from negative transfer and perform even worse than no transfer baseline. In Figure 4 we show the parameters learned for each classes in SMITLe in comparison with MULTIPLE. We can see that, when the prior knowledge is unrelated, SMITLe resists utilizing the prior knowledge and therefore shows almost identical accuracy to the no transfer baseline.

## 4.5 Transferring from mixed hypotheses

In real applications, extreme situation is rare. For most multisource transfer learning tasks, there should always be some related and useful sources as well as some unrelated ones. In this part, we show how SMITLe performs in the mixed sources.

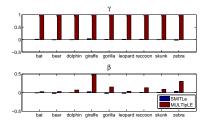

Figure 4: Experiment results for 10 classes, AwA. Horse is used as the new category. SMITLe can ignore unrelated prior knowledge.

Table 3: Average accuracy in percentage across all categories from AwA to Caltech. Examples in AwA are used to train prior models. Different number of training size is randomly selected from Caltech dataset.

# per category	5	10	15	20	25
No transfer	30.99	33.97	35.95	37.78	38.27
Source+1	17.89	18.69	18.79	19.69	19.39
MKTL	25.19	30.14	32.53	34.30	35.83
MULTIKT	27.60	32.19	34.51	36.78	37.79
MULTIpLE	29.79	33.45	35.49	36.77	37.43
SMITLe	30.93	34.13	36.09	38.01	38.46

From negative transfer experiments we see that the knowledge from AwA is unrelated to Caltech and vice versa. To generate mixed sources, we follow the settings in our positive transfer experiment, splitting the AwA dataset into two datasets, and replace the data of some categories in the source dataset with the data of Caltech. For example, if bat is considered as the new category and we have to replace 3 categories, we choose the data from 3 out of 9 categories (10 categories except for bat) in Caltech to replace the source data accordingly.

We show the performances across all categories of different algorithms in Table 4 and Table 5 where 3 and 4 categories in the source data are replaced by the data from Caltech respectively. From the tables we can see that in almost every case, SMITLe shows improved or equivalent performance than other baselines.

Table 4: Average accuracy in percentage across all categories from AwA to AwA&Caltech with different size of training set in target problem. Data of 3 classes in AwA is replaced by the data from Caltech in target problem.

# per category	5	10	15	20	25
no transfer	23.99	26.24	29.02	30.05	31.18
source+1	25.70	26.30	26.57	26.69	26.97
MKTL	25.30	27.59	30.42	31.01	31.97
MultiKT	25.53	27.94	30.48	31.36	32.31
MULTIpLE	28.11	29.61	31.34	32.18	32.89
SMITLe	28.75	30.48	32.30	33.06	33.71

Table 5: Average accuracy in percentage across all categories from AwA to AwA&Caltech with different size of training set in target problem. Data of 4 classes in AwA is replaced by the data from Caltech in target problem.

# per category	5	10	15	20	25
no transfer	24.02	26.25	29.06	30.07	31.20
source+1	23.23	23.80	24.03	24.21	24.47

MULTIpLE	26.50	28.33	30.27	31.29	32.12
SMITLe	27.20	29.33	31.40	32.31	33.11

#### 5 Conclusion

In this paper, we present a novel method called SMITLe that is able to transfer knowledge across different datasets and learn a new category. Inspired by previous work, SMITLe uses LS-SVM as the basic classification model and LOO for transfer parameter estimation. We demonstrate that SMITLe is able to converge at a logarithmic rate. We also prove that with the transfer parameters optimized by our novel objective function, SMITLe is able to avoid negative transfer which is a general issue for transfer learning. We carry out 3 sets of experiment that our algorithm would face in real world application. From the experimental results we can see SMITLe can consistently outperform other transfer baselines and achieve higher classification accuracy in different scenarios.

## **A** Convergence Analysis

Let  $\mu_1, ..., \mu_t$  be a sequence corresponding to  $\mu_t = (\sqrt{\lambda_1} \gamma^t, \sqrt{\lambda_2} \beta^t)$ . Problem (10) can be rewritten as:

$$J(\mu) = \frac{1}{2} \|\mu\|^2 + \sum_{i=1}^{l} \xi_i(\mu)$$

Let  $\Delta_t$  be the sub-gradient for  $J(\mu_t)$  and  $\mu^* = (\sqrt{\lambda_1}\gamma^*, \sqrt{\lambda_2}\beta^*)$  be the optimal solution for it. Assume that  $\|\Delta_t\| \leq G$ . According to Lemma 1 in [Shalev-Shwartz *et al.*, 2011], we have:

$$J(\mu_t) - J(\mu^*) \le \frac{G^2}{2t} (1 + \ln(t))$$
 (12)

This means that SMITLe converges at the rate of  $O(\frac{\log(t)}{t})$ .

## **B** Proof of avoiding negative transfer

Assume that  $\bar{\xi}_i$  is the multi-class loss of example  $x_i$  without utilizing any prior knowledge, i.e.  $\gamma = \beta = 0$ . Let  $\gamma^*, \beta^*$  be the optimal solution for Eq. (11) and  $\xi_i^*$  be the multi-class loss with respective to example  $x_i$ . Then for every example  $x_i \in \mathcal{X}$ , we have:

$$\sum_{i} \xi_{i}^{*} \leq \sum_{i} \bar{\xi}_{i}$$

*Proof.* When  $\gamma = \beta = 0$ , from Eq. (9) we can get:

$$\bar{\xi_i} = \max_{n} \left[ \varepsilon_{ny_i} - 1 + \frac{(\alpha'_{iy_i} - \alpha'_{in})}{\psi_{ii}^{-1}} \right]$$

For simplification, let  $\delta_i=1$  if i=N+1 and 0 otherwise, and  $\theta_{ij}=\alpha_{ij}''\left(1-\delta_j\right)/\psi_{ii}^{-1}$ . To find the minimum of the primal problem, we require:

$$\frac{\partial L}{\partial \xi_i} = 1 - \sum_n \eta_{in} = 0 \Rightarrow \sum_n \eta_{in} = 1 \tag{13}$$

$$\frac{\partial L}{\partial \gamma_n} = 0 \Rightarrow \gamma_n^* = \frac{1}{\lambda_1} \sum_i (\varepsilon_{ny_i} - \eta_{in}) \,\theta_{in} \tag{14}$$

$$\frac{\partial L}{\partial \beta_n} = 0 \Rightarrow \beta_n^* = \frac{1}{\lambda_2} \sum_{i,n} \frac{\eta_{in} \alpha''_{in}}{\psi_{ii}^{-1}} \left( \delta_{y_i} - \delta_n \right)$$
 (15)

As the strong duality holds, the primal and dual objectives coincide. Plug Eq (14) and (15) into Eq. (11), we have:

$$\sum_{i,n} \eta_{in} \left[ 1 - \varepsilon_{ny_i} + \hat{Y}_{in} \left( \gamma^*, \beta^* \right) - \hat{Y}_{iy_i} \left( \gamma^*, \beta^* \right) - \xi_i^* \right] = 0$$

Expand the equation above, we have:

$$\sum_{i,n} \eta_{in} \left[ \varepsilon_{n,y_i} - 1 + \frac{(\alpha'_{iy_i} - \alpha'_{in})}{\psi_{ii}^{-1}} - \xi_i \right]$$
$$= \lambda_1 \sum_r \|\gamma_r^*\|^2 + \lambda_2 \sum_r \|\beta_r^*\|^2 \ge 0$$

Rearranging the above, we obtain:

$$\sum_{i,n} \eta_{in} \left[ \varepsilon_{n,y_i} - 1 + \frac{(\alpha'_{iy_i} - \alpha'_{in})}{\psi_{ii}^{-1}} \right] \ge \sum_{i,n} \eta_{in} \xi_i = \sum_{i} \xi_i \text{ (16)} \frac{\text{IEEE Conference on, pages 951–958. IEEE, 2009.}}{[\text{Lu et al., 2015}]} \text{ Jie Lu, Vahid Behbood, Peng Hao, Hua}$$

The left-hand side of Inequation (16) can be bounded by:

$$\sum_{i,n} \eta_{in} \left[ \varepsilon_{ny_i} - 1 + \frac{(\alpha'_{iy_i} - \alpha'_{in})}{\psi_{ii}^{-1}} \right] 
\leq \sum_{i} \left( \sum_{n} \eta_{in} \max_{r} \left\{ \varepsilon_{ry_i} - 1 + \frac{(\alpha'_{iy_i} - \alpha'_{ir})}{\psi_{ii}^{-1}} \right\} \right) 
= \sum_{i} \left( \sum_{n} \eta_{in} \bar{\xi}_i \right) = \sum_{i} \bar{\xi}_i$$
(17)
